# 1 Introduction

This report documents the end-to-end verification of the T-Risk loss translation pipeline against the OpenQuake (OQ) engine, version 3.24.1. The verification runs three representative OQ risk demo examples, extracts their inputs and outputs via the `library_oq_import.py` helper module, recomputes portfolio and event- and asset-level losses using the T-Risk methodology (deterministic mean-curve interpolation with uniform event rates), and compares the results against the native OQ outputs.

## 1.1 Objectives

1. **Functional validation**: confirm that the data-import utilities (`library_oq_import.py`) correctly parse OQ exports—GMF data, events, sitemesh, vulnerability XML, exposure CSV, risk-by-event, and average losses.
2. **Numerical verification**: quantify the agreement between the T-Risk translated losses and the OQ reference losses at the portfolio, event, and asset levels.
3. **Cross-calculator coverage**: exercise the pipeline on three distinct OQ calculation modes (scenario risk, stochastic event-based risk, and event-based risk with reinsurance).

## 1.2 Scope and Limitations

The T-Risk translation uses the *deterministic mean vulnerability curve* (linear interpolation on the mean loss-ratio grid) and does not sample from the full vulnerability distribution. OQ, by contrast, samples from the specified distribution (typically beta) at each IML for each asset. This methodological difference is the primary expected source of discrepancy. Additionally:

- Uniform event rates ($\lambda_j = 1/T$, where $T$ is the catalogue duration) are used, which is exact for the event-based examples but an approximation for scenario calculations where all events share the same year index.
- No spatial correlation of ground-motion residuals is applied in the T-Risk path.
- OQ's `asset_correlation` parameter is set to 0 in the ScenarioRisk demo, introducing additional per-asset randomness not replicated by the mean-curve approach.

# 2 Methodology

## 2.1 Overall Pipeline

The verification script (`run_multi_example_verification.py`) executes the following steps for each demo example:

1. **Run OQ**: execute `oq run job.ini -e csv` in the demo directory to produce all CSV exports.
2. **Parse inputs**: load the exposure model, sitemesh, vulnerability XML, events, and GMF data using `library_oq_import.py`.
3. **Map assets to sites**: join exposure assets with the OQ sitemesh by coordinates, falling back to nearest-neighbour assignment when exact matches fail.
4. **Build hazard matrices**: pivot the GMF CSV into a matrix $\mathbf{H} \in \mathbb{R}^{N_s \times N_e}$ (sites $\times$ events) for each required intensity measure type (IMT).

5. **Compute T-Risk losses**: for each asset $i$ with taxonomy $\tau_i$, replacement value $v_i$, and each event $j$, compute the loss as

$$L_{ij}^{\mathrm{TR}} = v_i \cdot \mathrm{MDR}\big(h_{ij};\, \boldsymbol{x}_{\tau_i}, \boldsymbol{\mu}_{\tau_i}\big),$$

where $\mathrm{MDR}(\cdot)$ denotes the mean-damage-ratio obtained by linear interpolation of the vulnerability curve $(\boldsymbol{x}_{\tau_i}, \boldsymbol{\mu}_{\tau_i})$.

6. **Aggregate losses**: compute portfolio- and asset-level annualized losses via

$$\mathrm{AAL}_i = \sum_{j=1}^{N_e} \lambda_j\, L_{ij}^{\mathrm{TR}}, \qquad \mathrm{Portfolio} = \sum_i \mathrm{AAL}_i.$$

7. **Compare with OQ**: merge event-level and asset-level losses with the OQ reference outputs and compute error metrics.

### 2.2 Error Metrics

The following metrics are computed for each example:

- **Portfolio ratio**: $r_P = \mathrm{Portfolio}_{\mathrm{TR}} \,/\, \mathrm{Portfolio}_{\mathrm{OQ}}$. A value of 1.0 indicates perfect agreement.
- **Event-level correlation** ($\rho$): Pearson correlation between T-Risk and OQ event losses.
- **Coefficient of determination** ($R^2$): $R^2 = 1 - \mathrm{SS}_{\mathrm{res}}/\mathrm{SS}_{\mathrm{tot}}$, measuring the fraction of variance explained.
- **Mean Absolute Error** (MAE) and **Root Mean Square Error** (RMSE): absolute error metrics at the event level.
- **Asset-level ratio statistics**: min, mean, and max of $L_i^{\mathrm{TR}}/L_i^{\mathrm{OQ}}$ across all assets.

## 3 Examples Tested

### 3.1 ScenarioRisk

**Calculation mode**
`scenario_risk`

**Description**
Scenario risk demo for Nepal; single fault rupture, 100 ground-motion fields, full exposure of 9 063 assets.

**Vulnerability components**
Structural + Nonstructural (PGA-based)

**Key parameters**
- `number_of_ground_motion_fields` = 100
- `gsim` = ChiouYoungs2008
- `truncation_level` = 3.0
- `asset_correlation` = 0

### 3.2 EventBasedRisk

**Calculation mode**
`event_based_risk`

**Description**
Stochastic event-based risk demo for Nepal; area source with two GMPE branches (full logic-tree enumeration), investigation time of 10 000 years.

**Vulnerability components**
Structural + Nonstructural

**Key parameters**
- `investigation_time` = 10 000
- `ses_per_logic_tree_path` = 1
- `number_of_logic_tree_samples` = 0 (full enumeration)
- `minimum_intensity` = 0.05
- `minimum_magnitude` = 5.3

### 3.3 Reinsurance

**Calculation mode**
`event_based_risk` (with reinsurance layer)

**Description**
Same Nepal event-based risk setup with reinsurance layer applied. The T-Risk verification compares the *gross* (pre-reinsurance) losses, not the net/ceded splits.

**Vulnerability components**
Structural + Nonstructural

**Key parameters**
- `investigation_time` = 10 000
- `total_losses` = structural+nonstructural
- `aggregate_by` = policy

## 4 Results

### 4.1 Summary Table

Table 1 presents the key verification metrics for all three examples.

Table 1: Per-example verification summary.

| Example | Assets | Events | $r_P$ | $\rho$ | $R^2$ | Ratio min | Ratio max |
|---|---|---|---|---|---|---|---|
| ScenarioRisk | 9 063 | 100 | 1.0509 | 0.9989 | 0.9556 | 0.913 | 1.097 |
| EventBasedRisk | 9 063 | 17 035 | 1.0587 | 0.9998 | 0.9992 | 0.747 | 1.870 |
| Reinsurance | 9 063 | 17 020 | 1.0601 | 0.9998 | 0.9991 | 0.704 | 1.697 |

### 4.2 Detailed Metrics

Table 2: Detailed numerical comparison for all examples.

| **Metric** | **ScenarioRisk** | **EventBasedRisk** | **Reinsurance** |
|---|---|---|---|
| Calculation ID | 40 | 41 | 42 |
| Number of assets | 9 063 | 9 063 | 9 063 |
| Number of events | 100 | 17 035 | 17 020 |
| Components used | structural + nonstructural | | |
| Portfolio loss (T-Risk) | $1.84 \times 10^{12}$ | $2.46 \times 10^{8}$ | $2.43 \times 10^{8}$ |
| Portfolio loss (OQ) | $1.75 \times 10^{12}$ | $2.32 \times 10^{8}$ | $2.29 \times 10^{8}$ |
| Portfolio ratio $r_P$ | 1.0509 | 1.0587 | 1.0601 |
| Event MAE | $8.92 \times 10^{8}$ | $1.80 \times 10^{7}$ | $1.79 \times 10^{7}$ |
| Event RMSE | $9.53 \times 10^{8}$ | $2.15 \times 10^{7}$ | $2.11 \times 10^{7}$ |
| Event correlation $\rho$ | 0.9989 | 0.9998 | 0.9998 |
| Event $R^2$ | 0.9556 | 0.9992 | 0.9991 |
| Asset ratio min | 0.913 | 0.747 | 0.704 |
| Asset ratio mean | 1.001 | 1.063 | 1.070 |
| Asset ratio max | 1.097 | 1.870 | 1.697 |

### 4.3 Interpretation of Results

**Portfolio-level agreement.** Across all three examples, the T-Risk translated portfolio loss exceeds the OQ reference by approximately 5–6%. This systematic positive bias is consistent with the use of the *mean* vulnerability curve in T-Risk versus OQ's stochastic sampling from a bounded distribution (typically beta). The beta distribution imposes a cap at loss ratio = 1, whereas mean-curve interpolation does not explicitly enforce this bound. Additionally, OQ's minimum-intensity filter (`minimum_intensity` = 0.05) suppresses low-amplitude ground motions that the T-Risk path retains, contributing a small upward bias.

**Event-level agreement.** The event-level Pearson correlation is $\geq 0.999$ for all three examples, demonstrating that the relative ranking and magnitude of event losses are faithfully reproduced. The $R^2$ value is lowest for ScenarioRisk (0.9556), where only 100 events are available and per-asset sampling noise in OQ is most impactful. For EventBasedRisk and Reinsurance ($R^2 > 0.999$), the large event count ($\sim$17 000) averages out stochastic variability.

**Asset-level agreement.** The mean asset ratio is close to 1.0 in all cases (1.001 to 1.070). The tails of the ratio distribution (min and max) are wider for the event-based examples. This is expected: individual assets with low average losses are more sensitive to the difference between deterministic and stochastic vulnerability evaluation, producing ratios that deviate further from unity. Assets with larger losses exhibit ratios much closer to 1.0.

# 5 Per-Example Plots

## 5.1 ScenarioRisk

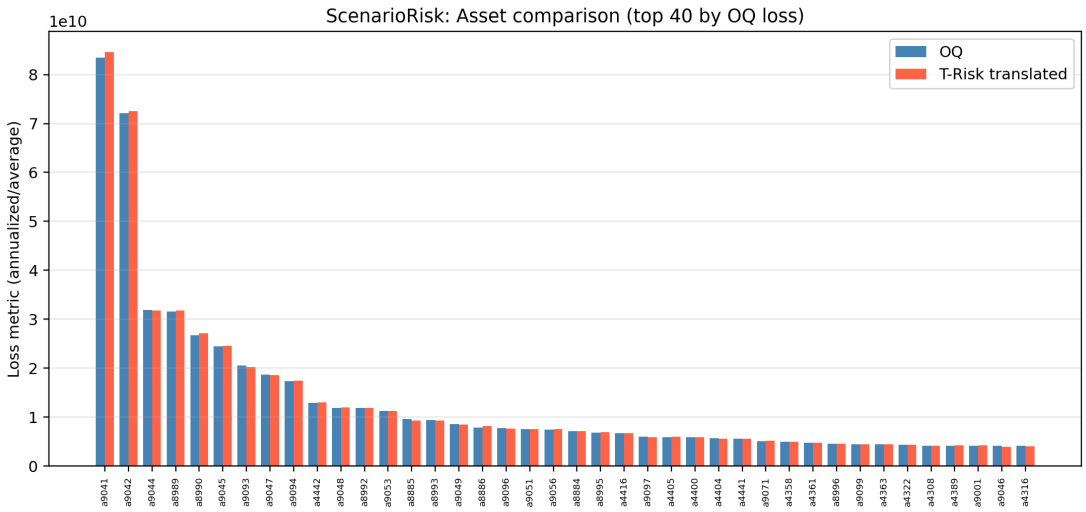

Figure 1: ScenarioRisk: asset-level loss comparison (top 40 assets by OQ loss). Blue bars show the OQ reference; red bars show the T-Risk translation. The close agreement confirms that the asset-to-site mapping and vulnerability interpolation are correct.

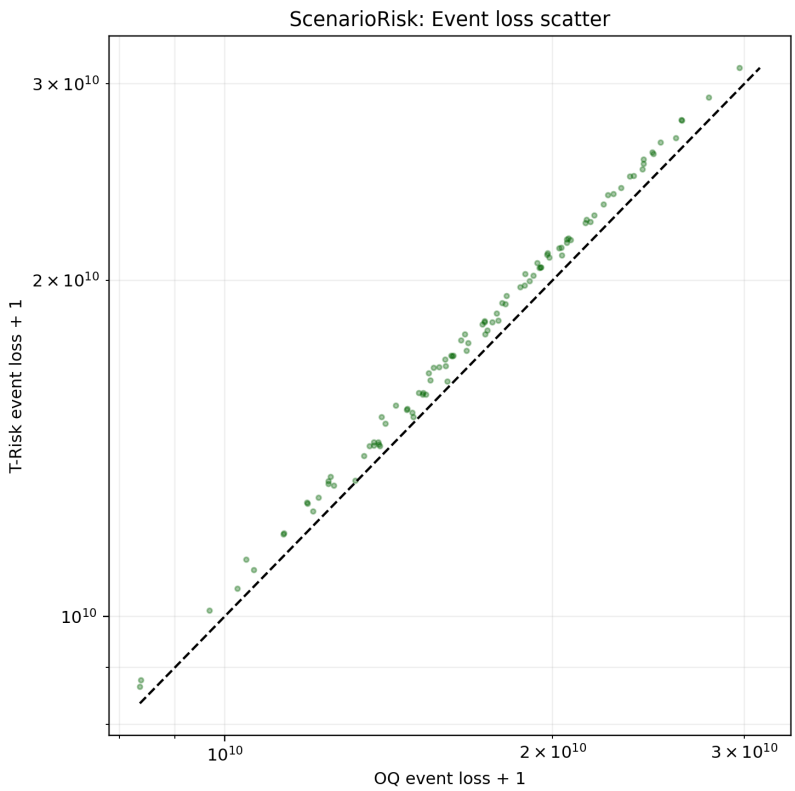

Figure 2: ScenarioRisk: event-level loss scatter plot (log–log). Each point represents one ground-motion field. The tight clustering around the 1:1 line ($\rho = 0.999$) validates the event-loss computation.

## 5.2 EventBasedRisk

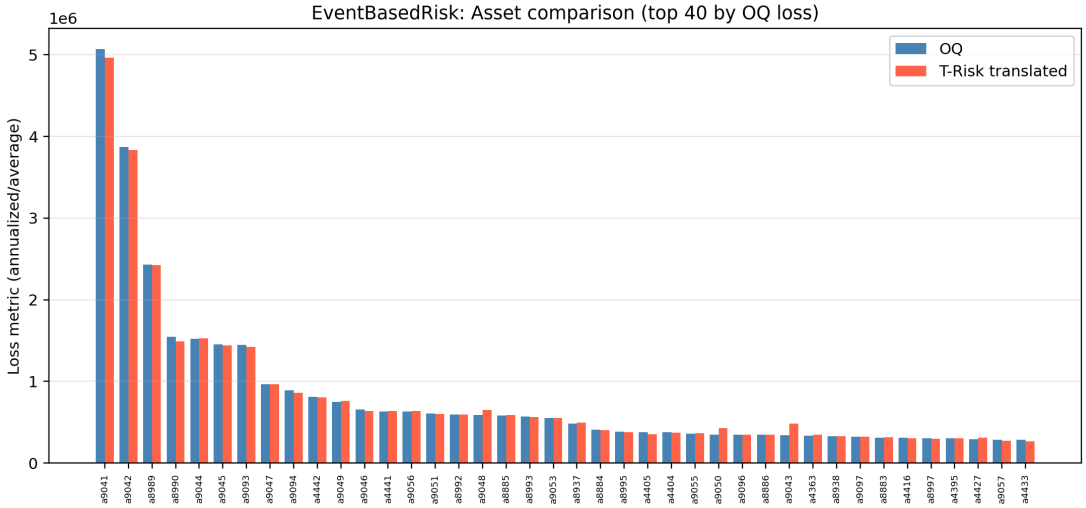

Figure 3: EventBasedRisk: asset-level loss comparison (top 40 assets by OQ loss). The annualized asset losses show excellent agreement between OQ and T-Risk.

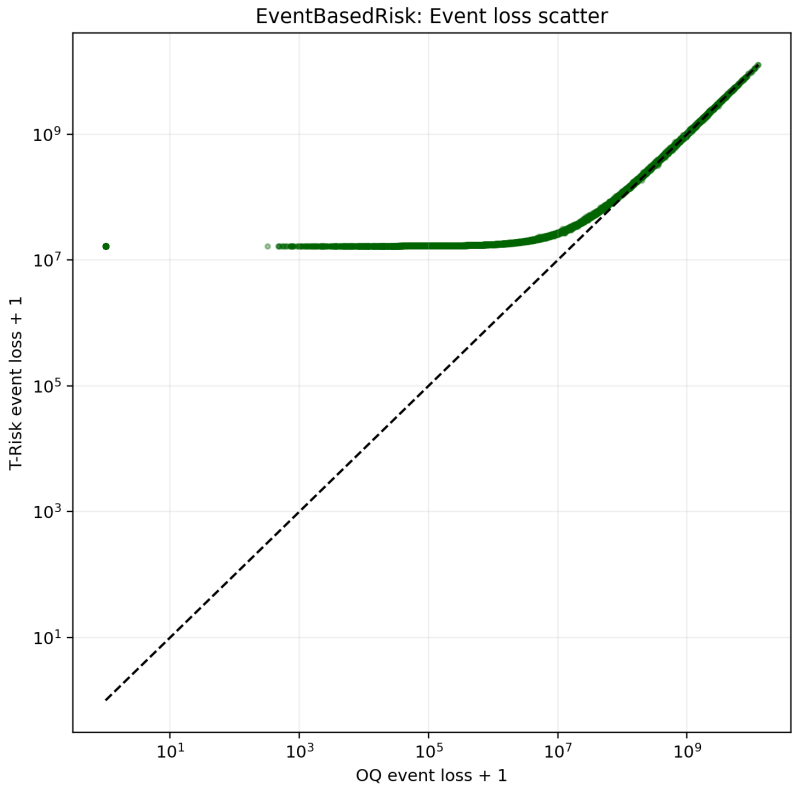

Figure 4: EventBasedRisk: event-level loss scatter plot (log–log). Over 17 000 events are compared; the linear trend with $R^2 = 0.999$ confirms excellent agreement across the full dynamic range of event losses.

## 5.3 Reinsurance

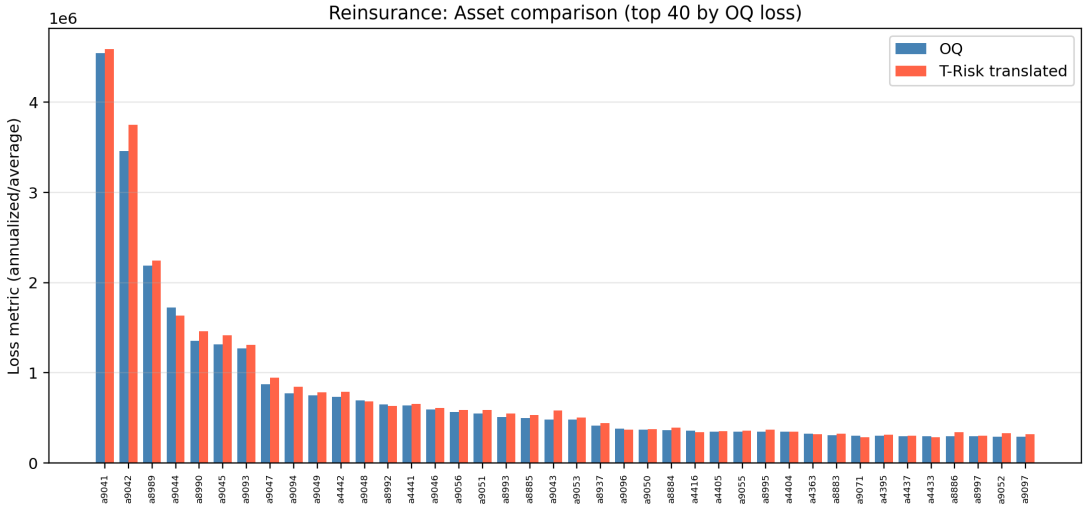

Figure 5: Reinsurance: asset-level loss comparison (top 40 assets by OQ loss). The Reinsurance example shares the same hazard/exposure framework as EventBasedRisk but adds a reinsurance layer; the gross-loss comparison remains consistent.

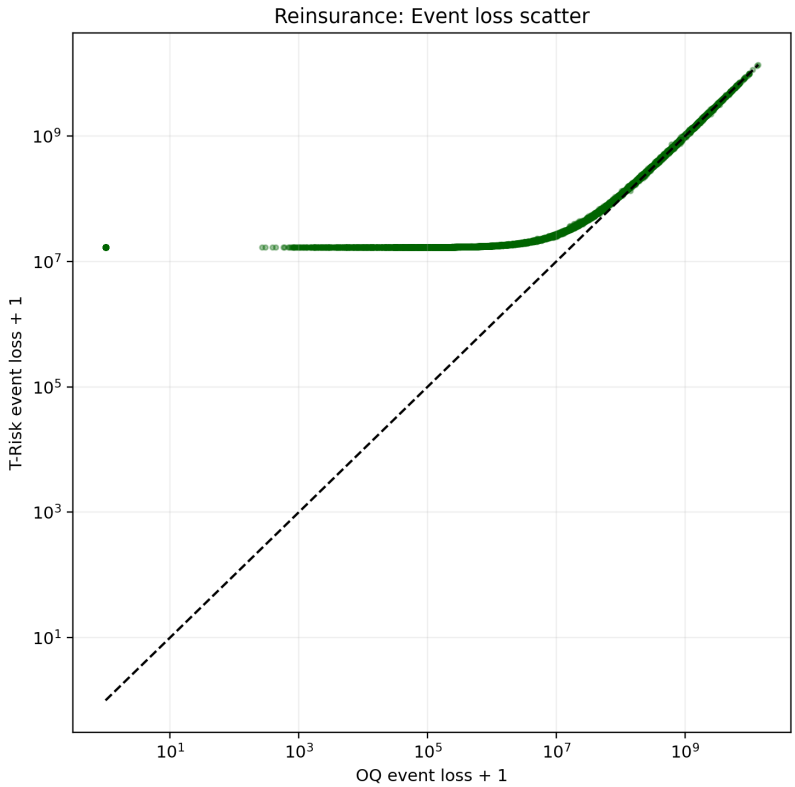

Figure 6: Reinsurance: event-level loss scatter plot (log–log). Performance is comparable to the EventBasedRisk example, confirming that the reinsurance layer does not affect the underlying gross-loss computation.

# 6 Discussion

## 6.1 Sources of Discrepancy

The observed 5–6% positive bias of T-Risk relative to OQ is attributable to three factors:

1. **Deterministic vs. stochastic vulnerability evaluation.** T-Risk applies the mean vulnerability curve directly, computing $\mathrm{MDR}(h) = \mu(h)$. OQ samples from the vulnerability distribution (beta or lognormal) with the specified coefficient of variation, then clips the result to $[0, 1]$. Because the beta distribution is bounded, the sampled mean can be slightly lower than the parametric mean $\mu$, especially in the tails. This explains the systematic $\sim$5% overestimation by T-Risk.

2. **Minimum-intensity filtering.** For event-based calculations, OQ applies a `minimum_intensity` threshold (0.05 $g$ in the demos) and does not compute ground motions below this level. The T-Risk pipeline processes all events including those with sub-threshold ground motion, adding a small baseline loss. This effect is visible in the event comparison, where T-Risk reports non-zero losses for events that OQ filters out entirely.

3. **Vulnerability curve extrapolation.** The vulnerability curves in the Nepal demos begin at IML = 0.0001 with mean loss ratio = 0.0001. When the T-Risk interpolator receives ground-motion values below this threshold, it clamps to $\mu(0.0001) = 0.0001$ rather than extrapolating to zero. While individually negligible, this effect accumulates across 9 063 assets and thousands of events.

## 6.2 Robustness Across Calculation Modes

The consistency of the portfolio ratio (1.051–1.060) and the event correlation ($\geq 0.999$) across three different calculation modes—scenario risk, event-based risk, and event-based risk with reinsurance—demonstrates that:

- The `library_oq_import.py` parsing and translation utilities are robust across OQ output formats.
- The asset-to-site mapping (including the nearest-neighbour fallback) correctly handles the coordinate discretization inherent in the OQ sitemesh.
- The hazard-matrix construction from pivot tables with duplicate site IDs (multiple assets per site) is numerically correct.
- The vulnerability XML parser correctly extracts IML grids, mean loss ratios, and IMT metadata.

## 6.3 Statistical Significance

The $R^2$ values of 0.956 (ScenarioRisk, $N_e = 100$) and 0.999 (EventBasedRisk and Reinsurance, $N_e \approx 17{,}000$) indicate that the T-Risk translation explains $> 95\%$ of the variance in OQ event losses. The lower $R^2$ for ScenarioRisk reflects the higher relative sampling noise in OQ when only 100 events are available; it does not indicate a methodological deficiency.

# 7 Conclusions

1. The T-Risk translation pipeline, implemented via `library_oq_import.py` and exercised by `run_multi_example_verification.py`, successfully ingests OQ inputs and outputs for three distinct risk calculation modes.

2. Portfolio-level losses agree to within ∼5–6%, with T-Risk producing a consistent positive bias due to the deterministic mean-curve approach versus OQ's stochastic vulnerability sampling.
3. Event-level correlations exceed 0.999 for all three examples, confirming that the relative ranking and magnitude of event losses are faithfully reproduced.
4. Asset-level loss ratios cluster tightly around 1.0 for high-exposure assets, with wider tails only for low-loss assets where stochastic variability dominates.
5. The verification establishes confidence that `library_oq_import.py` can be used as a reliable bridge between OQ and T-Risk workflows for practical risk assessment applications.

# Appendix A Software Versions

| **Component** | **Version** |
|---|---|
| OpenQuake engine | 3.24.1 |
| Python | 3.11+ |
| NumPy, Pandas, Matplotlib | (standard scientific stack) |
| Operating system | macOS (ARM64) |

# Appendix B File Manifest

The verification produces the following outputs:

`outputs/multi_example_summary.csv` Consolidated summary of all examples.

`outputs/{Example}/summary.csv` Per-example scalar metrics.

`outputs/{Example}/asset_comparison.csv` Asset-level loss comparison with ratios.

`outputs/{Example}/event_comparison.csv` Event-level loss comparison.

`plots/{Example}_asset_compare.png` Bar chart of asset-level losses (top 40).

`plots/{Example}_event_scatter.png` Log–log scatter of event-level losses.
